Abstract

TNFα is one of the inflammatory cytokines which plays an important role in activating the Caspase and inducing the apoptosis. This cytokine which is secreted in inflammations, induces the NO production in macrophages and leads to differentiation of the macrophages to the epithelioid and giant cells. One of the most important factors which stimulates the TNFα secretion, is LPS and that antigen (LPS) is the mitogen of the T1-1 in the B lymphocytes and as a result, many of macrophages such as microglia cells proliferate. Microglia is the smallest non-neuronal cells in the CNS and responds to the inflammations in the CNS. One of the factors in developing the Parkinson disease is TNFα which is secreted of the microglia cells and destroys the dopaminergic neurons in substantia nigra. In Parkinson disease, microglia cells leave the resting form and achieve the plastic amoeboid morphology (In the resting form, microglia cells have homeostatic roles and eliminate the neurotoxins and dead cells). Finally, the levels of the Caspase 3 and 8 increase and the condition is prepared for the apoptosis of the neuron and in both chronic and acute forms, the levels of the TNFα increase in the cerebrospinal fluid (CSF).
